# QMST 5367

# Machine Learning

# Plant Image Processing

# Hypothetical Business Scenario

- Startup company developing an app to identify the plants using machine learning upon taking a photo
- Target customers: Girl/Boy Scout groups, avid hikers, forest rangers, hobbyist foragers, etc.
- We have premium and free services
  - Premium service: expanded plant image recognition
  - Free service: plant leaf recognition will be limited to 3 classifications
  - Tomato, raspberry, poison ivy

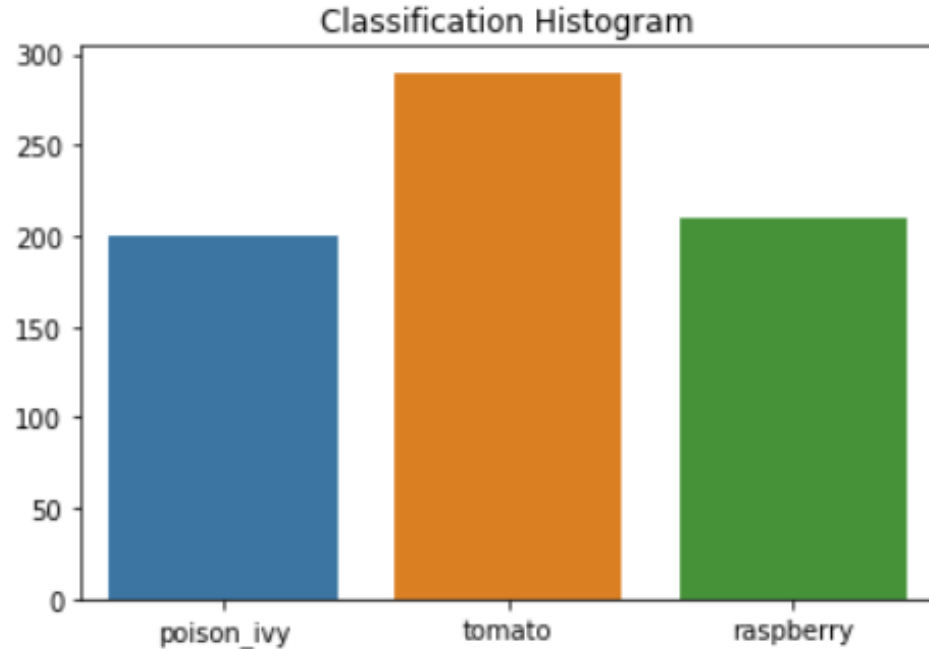

## Datasets and ML Algorithm

- We gathered 200 - 300 images per classification: tomato, raspberry, poison ivy
- By training our model with the image datasets, we can accurately identify types of plants. This removes effort and time to research plant information and type
- App will use supervised machine learning since in the end the user knows the plant type. The algorithm will choose the best match using statistical significance

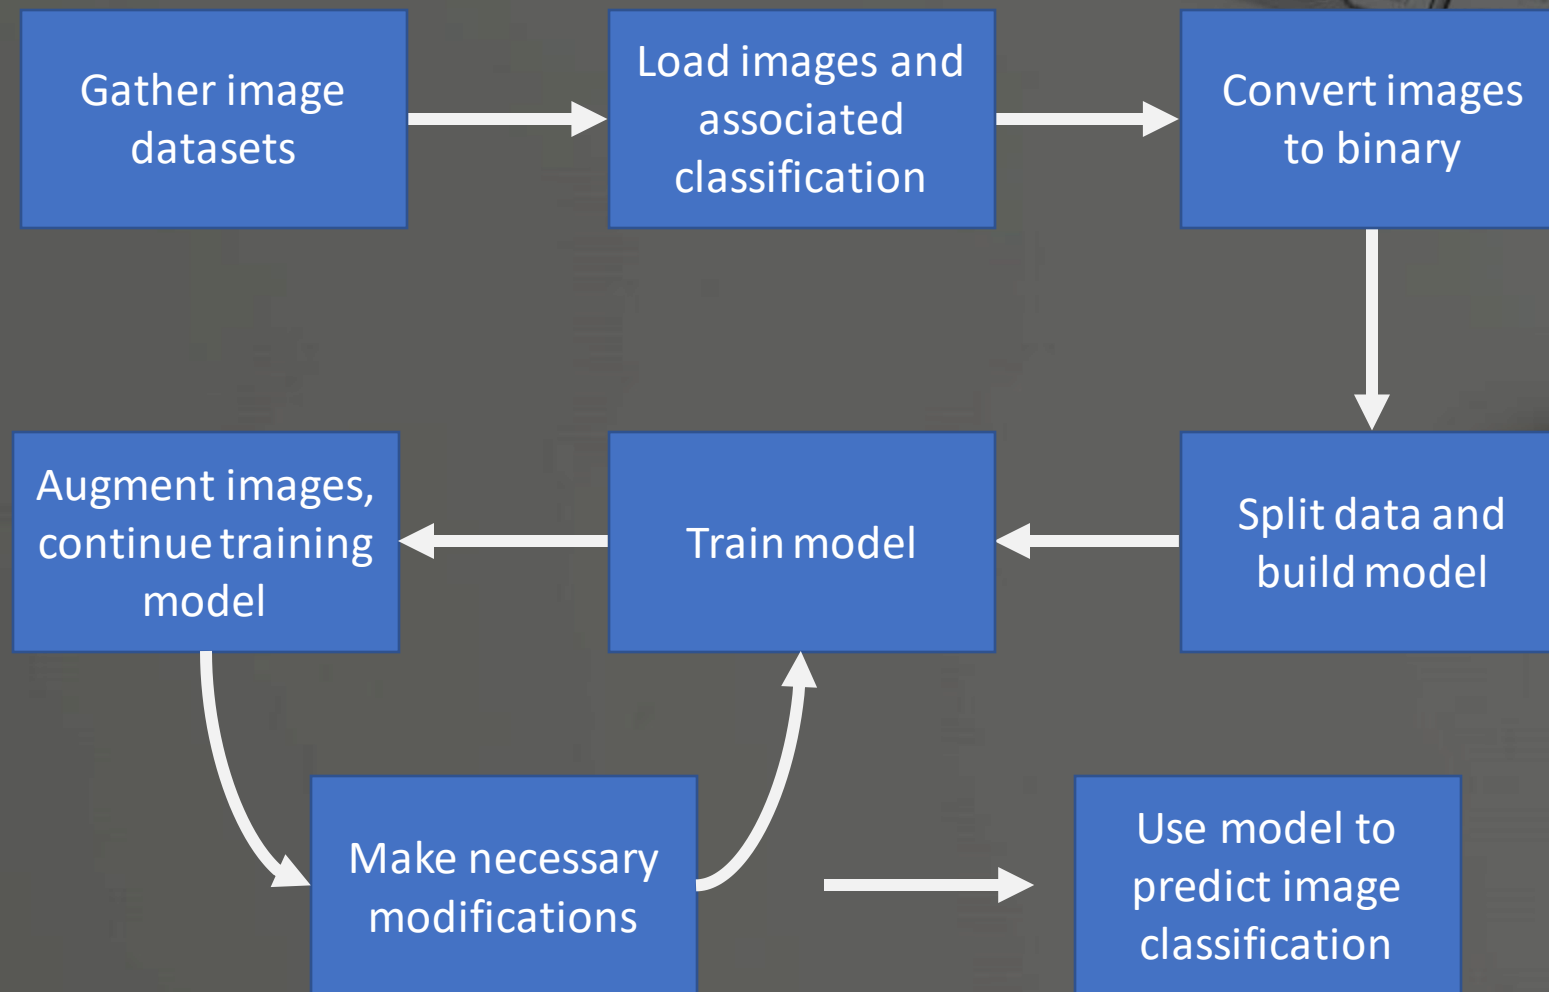

# Image Visualization / Transformation

- Original image → Black and White image

# Image Processing Flowchart

# Layers of Model

- Model consists of sequential layers of calculations – forming a neural network in order of input to output
  - Activation – determines output of neural network
  - Batch Normalization – helps prevent overfitting and normalize data
  - Flatten – before passing data to next layer we flatten to 1 dimension
  - Dense – takes outputs from previous layer and provides them for next layer

- Actual Value of Target: 13
- Error: Predicted - Actual = -4

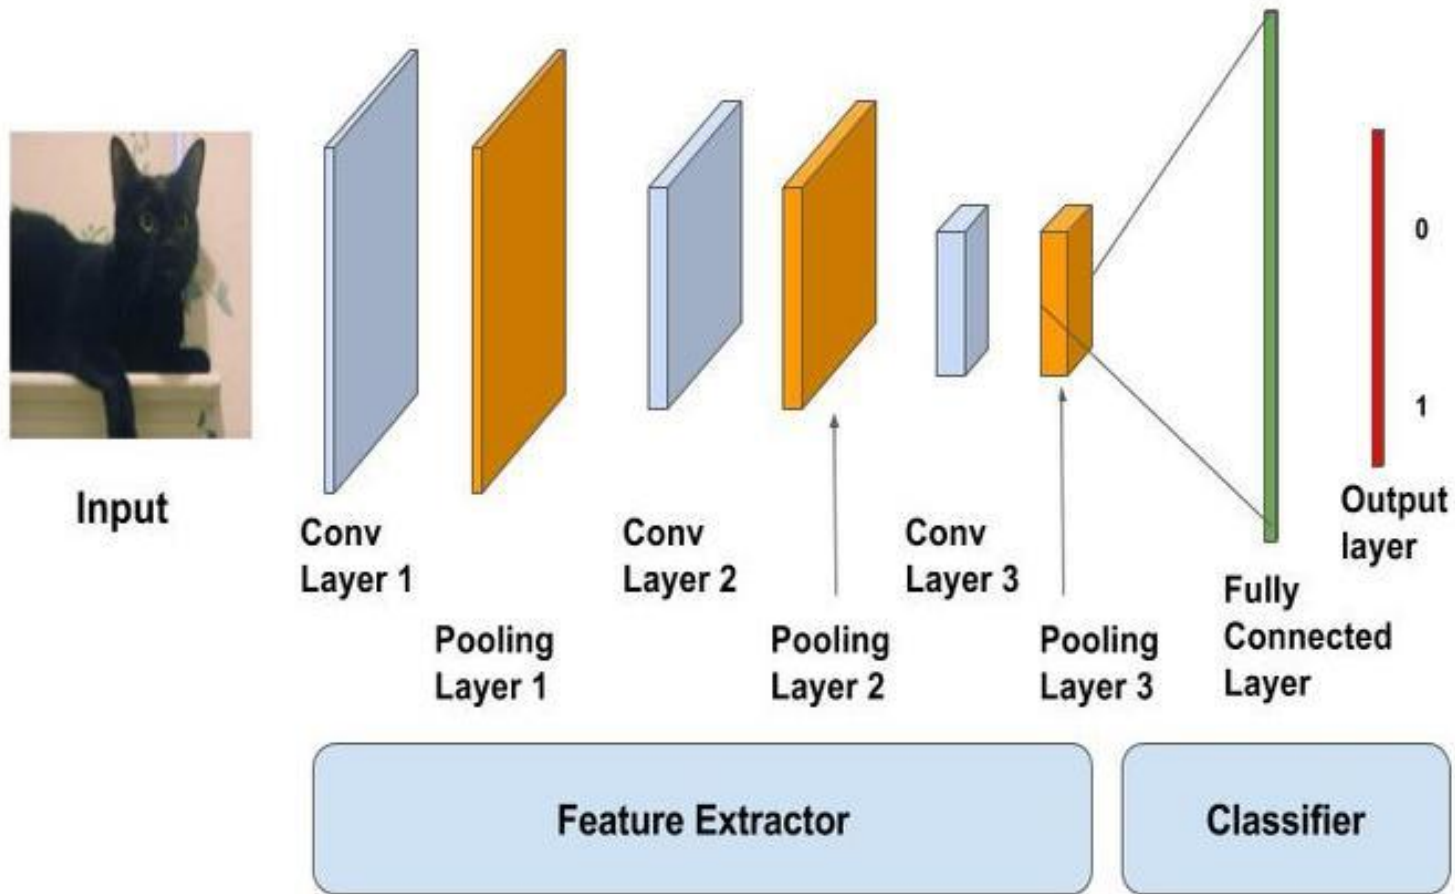

# Convolutional Neural Network (CNN)

- CNNs have high accuracy for image processing and classification
- Used mainly used keras, sklearn, and cv2 packages to process images
  - Convert images to binary arrays for computer to interpret and analyze
  - Design model by adding layers to neural network
  - Optimize model

Raw data

Low-level features

Mid-level features

High-level features

# Training Our Model

- Augment Data
- Split data into training and testing
- Fit model
- Evaluate model

# Model Optimization

---

- Adam function is an optimization process that helps reduce prediction error
  - Adapts and molds the most accurate model by adjusting CNN weights
  - Has best accuracy in enhancing the CNN ability in classification
- Epoch is the number of times we pass the data through the model
  - Like solving same or similar problems again and again -- similar images easier to classify
  - It helps the model learn from a smaller datasets and with image transformations

# Model Accuracy and Fit

- We are most concerned about the value accuracy of a model
  - Use statistical significance in app to identify plant leaf class
- Using image transformation and Adam optimization, we set epochs to 7 to achieve high model accuracy
- As a result, model is 84% accurate at classifying tomato, poison ivy, and raspberry leaf images

# Model Accuracy and Loss

- Blue: Training data
- Red: Testing data

# Validation

**The training accuracy is higher than validation data**

This is normal and expected

Model has seen the training data before and can easily identify images from training dataset

**Training data loss is less than validation loss.**

Normal and expected -- validation loss decreases with more epochs

Model has NOT seen the validation data before and is less familiar with those images

# Prediction

- We have images that we did not run through our model
- We randomly selected an image from a set of 40 images
- The model accurately predicts the class of plant

# Improvements

- Classify more plants
  - Currently have 3 classifications
  - Increase plant leaf classifications for premium service
- Add more images (more data) (more diverse environment)
- Augmenting the photos for training
- Merge Layers, Stack Models
